5 2022-12-27

6 **Abstract**

7 Despite the extensive literature focusing on Acheulean handaxes, especially the sources
8 and meaning of their morphological variability, many aspects of this topic remain elusive.
9 Archaeologists cite many factors that contribute to the considerable variation of handaxe
10 morphology, including knapper skill levels and mental templates. Here we present results from
11 a multidisciplinary study of Late Acheulean handaxe-making skill acquisition involving thirty
12 naïve participants trained for up to 90 hours in Late Acheulean style handaxe production and
13 three expert knappers. We compare their handaxe to the Late Acheulean handaxe assemblage
14 from Boxgrove, UK. Through the principal component analysis of morphometric data derived
15 from images, our study suggested that knapper skill levels and mental templates have a
16 relatively clear manifestation in different aspects of handaxe morphology. The former relates
17 to cross-sectional thinning (PC1), while the latter refers to handaxe elongation and pointedness
18 (PC2). Moreover, we also evaluated the effects of training using the data from a 90-hour-long
19 knapping skill acquisition experiment. We found that reaching the skill level of modern experts
20 requires more training time than was permitted in this extensive and long-running training
21 program. ¶

40 1 Introduction

41 The morphological variability of Acheulean handaxes has been one of the most well-studied
 42 and well-published topics in paleolithic archaeology (Key & Lycett, 2019; Petraglia & Korisettar,
 43 1998; White, 1998). Despite the recurrent narrative emphasizing the homogeneity and longevity
 44 of handaxe assemblages on a global scale and the conservatism behind this phenomenon that
 45 evokes genetic explanations (Corbey et al., 2016; Corbey, 2020; Richerson & Boyd, 2005; Sterelny,
 46 2004), many researchers have recognized the diversity within what has been deemed as a unified
 47 Acheulean “tradition” and tried to dissect the sources and meaning of this variation (Lycett &
 48 Gowlett, 2008; Nowell, 2002; Nowell & White, 2010; Sharon et al., 2011). More specifically, a
 49 complex suite of interconnecting factors (Lycett & Cramon-Taubadel, 2015) have been identified
 50 to contribute to handaxe morphological variation, including but not limited to raw material
 51 variability (Eren et al., 2014; Lycett et al., 2016; McNabb & Cole, 2015; Sharon, 2008), percussor
 52 properties (Shipton et al., 2009), functional differences (Key et al., 2016; Key & Lycett, 2017; Lycett
 53 & Gowlett, 2008; Machin et al., 2007; White & Foulds, 2018), reduction method/intensity (Shipton
 54 et al., 2009; Shipton & Clarkson, 2015), time budgets (Schillinger et al., 2014b), learning processes
 55 (Kempe et al., 2012; Lycett et al., 2016), social signaling (Kohn & Mithen, 1999; Spikins, 2012),
 56 aesthetic preferences (Gowlett, 2021; Le Tensorer, 2006), knapper skill levels (Caruana & Herries,
 57 2021; Herzlinger et al., 2017; Stout et al., 2014), and mental templates (García-Medrano et al., 2019;
 58 Hutchence & Scott, 2021; Schillinger et al., 2017). From this extensive list, knapper skill levels and
 59 mental templates have been repeatedly mentioned and discussed in the now extensive corpus

60 of handaxe studies, and Boxgrove handaxes have been one of the most studied assemblages
61 from these two angles. Of particular attention here are the experimental works conducted by
62 Stout et al. (2014) focusing on inferring knapping skill level and Garcia-Medrano et al. (2019)
63 identifying the mental template of the Boxgrove assemblage. Our paper combines these two
64 perspectives and provides novel insights to the same archaeological assemblage by comparing it
65 with experimentally made handaxes.

66 In its classical definition, the term mental template indicates that the “idea of the proper form
67 of an object exists in the mind of the maker, and when this idea is expressed in tangible form in
68 raw material, an artifact results” (Deetz, 1967: 45). This concept lies at the very foundation of the
69 cultural-historical approach in that the identification of archaeological cultures is based on the
70 existence of distinct mental templates in a given spatial-temporal framework. Early researchers,
71 whether explicitly or implicitly, often endorsed this conceptual framework and actively applied it
72 in the typological analysis of handaxes at the regional level (Roe, 1969; Wenban-Smith et al., 2000;
73 Wenban-Smith, 2004). Combined with the production of large flakes, the emergence of mental
74 templates (or “imposed form”) has been recognized as a major technological innovation of the
75 Acheulean compared with the Oldowan (Isaac, 1986). For a decade or so, this concept has been
76 less frequently used, since it was criticized for a) its normative and static assumption (Lyman
77 & O’Brien, 2004), b) ignoring other competing factors such as raw material constraints (White,
78 1995), and c) being constrained by the basic fracture mechanics and design space of bifacial
79 technology (Moore, 2011; Moore & Perston, 2016). To avoid the historical baggage associated
80 with this controversial term, some researchers developed alternative frameworks such as “design
81 imperatives” derived from utilitarian and ergonomic principles, which refers to a set of minimum
82 features shared by all handaxes including their glob-but, forward extension, support for the
83 working edge, lateral extension, thickness adjustment, and skewness (Gowlett, 2006; Wynn &
84 Gowlett, 2018). The major difference between the concepts of design imperatives and mental
85 templates lies in the fact that the former does not necessarily require the presence of explicit
86 internal representations of form, where the shape of handaxes can instead emerge “through the
87 coalescence of ergonomic needs in the manipulation of large cutting tools (Wynn, 2021: 185).”
88 Recently, researchers have actively addressed the above-mentioned critiques and reconcep-
89 tualized the concept of mental template in the study of handaxe morphology. Regarding the
90 normative and static assumptions, Hutchence and Scott (2021), for example, leveraged the theory

91 of “community of practice” (Wenger, 1998) to explain the stability of Boxgrove handaxe design
92 across multiple generations. From this perspective, social norms behind the consolidated ma-
93 terial expressions were developed and negotiated by individuals in a group who have a shared
94 history of learning. They further emphasized that emergent actions of individual knappers also
95 contribute greatly to the shape of Boxgrove handaxes but they were simultaneously constrained
96 by the imposition of social norms. This view also somewhat echoes the “individualized memic
97 construct” proposed by McNabb et al. (2004), which highlighted the influence of individual
98 agency that is complementary to the traditionally favored explanation of social learning. As
99 for the critique towards confounding factors explaining morphological variability, raw material
100 is often treated as an important variable to be controlled at the very beginning of a research
101 design focusing on mental templates. This is best exemplified by an experimental study of
102 García-Medrano et al. (2019), where they carefully chose experimental nodules mirroring those
103 found in the Boxgrove archaeological assemblage in composition, size, and shape. Regarding
104 the critique of design space constraint, Moore and Perston’s experiment (2016) suggested that
105 bifaces can be manufactured through flake removals dictated by a random algorithm. However,
106 Moore (2020: 656-657) also suggested that these random experiments cannot produce “attributes
107 like the congruent symmetries of handaxes seen in the Late Acheulean.” In short, when exer-
108 cised with proper caution, the concept of mental templates still has its value in our study of
109 handaxe morphological variation, which can be further dissected into a series of shape variables
110 corresponding to pointedness, elongation, and cross-sectional thinning among other things.

111 Following the reconceptualization of the mental template as a more flexible and interactive
112 concept, one possible way of defining skill is the capacity for a knapper to realize mental templates
113 using the resources available (Roux et al., 1995: 66). This version of conceptualization, particularly
114 relevant when it comes to motor skills such as knapping, can be dismantled into two mutually
115 dependent aspects, namely the intentional aspect (goal/strategic planning) and the operational
116 aspect (means/motor execution) (Connolly & Dalgleish, 1989). It also roughly corresponds
117 to the well-known dichotomy developed by French lithic analysts of “*connaissance*” (abstract
118 knowledge) and “*savoir-faire*” (practical know-how) (Pelegrin, 1993). As Stout (2002: 694) noted,
119 the acquisition of skill is deeply rooted in its social context, and it is not composed of “some
120 rigid motor formula” but “how to act in order to solve a problem”. This ecological notion of skill
121 somewhat mirrors Hutchence and Scott’s (2021) reconceptualization of the mental template
122 in that they both refute the idea that technology is simply an internal program expressed by

the mind and they prefer a dynamic approach emphasizing the interaction between perception and action. The manifestations of skill in materialized form display a great amount of variation, but ethnoarchaeological studies have repeatedly suggested that skills can be improved through practice as perceived by local practitioners. It is thus possible to evaluate the skill levels reflected in knapping products (Roux et al., 1995; Stout, 2002). When contextual information is less readily available as in the Late Acheulean archaeological assemblages, how to properly operationalize and measure knapping skills has been a methodological issue receiving much attention among archaeologists (Bamforth & Finlay, 2008; Kolhatkar, 2022). In addition to measurements that can be almost applied in any lithic technological system such as raw materials, platform preparation, as well as hinges, in the context of handaxe technology, symmetry (Hodgson, 2015; Hutchence & Debackere, 2019) and cross-sectional thinning (Caruana, 2020; Pargeter et al., 2019; Stout et al., 2014; Whittaker, 2004: 180-182) have been frequently quoted as reliable and distinctive indicators of the skill level as supported by several experimental studies. These two features have also been commonly used as standards for dividing Early Acheulean and Late Acheulean (Callahan, 1979; Clark, 2001; Schick & Toth, 1993).

Drawing on these two lines of literature, we aim to explore the possibility of dissecting the interaction of skill level and mental template through a comparative study of an archaeological handaxe assemblage known for its remarkable high skill level, a reference handaxe collection produced by modern knapping experts, and an experimental handaxe sample produced by modern novice knappers. We generated the novice handaxe collection from a 90-hour skill acquisition experiment providing the opportunity to introduce the diachronic dimension of training time and interrogate its impact on the variables of interest. As such, we propose the following two interconnected research questions in this article: 1) Can skill level and mental templates be efficiently detected from handaxe morphometric data? Accordingly, we hypothesize that the morphometric variables showing overlap between Boxgrove and expert samples while being markedly different from novice samples reflect skill level differences, and all three group should show a similar mental template since this is the common target. 2) How does training affect novices' performance in these two aspects? Our hypothesis is that throughout the training the novice samples should become more similar to expert samples in both skill level and mental template.

153 **2 Materials and methods**

154 **2.1 Boxgrove handaxe collection**

155 The archaeological site of Boxgrove is located in the former Eartham quarry, Boxgrove, West Sussex,
156 featuring a long sequence of Middle Pleistocene deposits (Pope et al., 2020; Roberts & Parfitt,
157 1998). This 500-ka-old site has documented exceedingly rich details of Lower Paleolithic hominin
158 subsistence behaviors (Smith, 2013, 2012) and their paleoenvironmental contexts (Holmes et al.,
159 2010). In addition to the presence of one of the earliest hominin fossil (*Homo heidelbergensis*,
160 Hillson et al., 2010) and bone assemblages with anthropogenic modifications in northern Europe
161 (Bello et al., 2009), Boxgrove is mostly known for its large sample size of Late Acheulean-style flint
162 handaxes and the high skill level reflected in their manufacture (Figure 1). As such, it has received
163 wide research attention in the past two decades regarding the relationships between technology,
164 cognition, and skills (García-Medrano et al., 2019; Iovita et al., 2017; Iovita & McPherron, 2011; Key,
165 2019; Shipton & Clarkson, 2015; Stout et al., 2014). To identify the morphological manifestation of
166 knappers' skill level in our study, we selected a complete handaxe assemblage (n=326) previously
167 analyzed and reported in digital formats by Iovita and McPherron (2011), which is currently
168 curated at the Franks House of the British Museum (Iovita et al., 2017). The digital photographs
169 are taken of each handaxe at a 90° angle, which was oriented with the tip to the right of the photos,
170 and the camera faces the most convex surface of the handaxe (Iovita & McPherron, 2011).

Figure 1: A selection of Boxgrove handaxes and modern replicas produced by experts and novices.

171 **2.2 Experimental handaxe collection**

172 The handaxe experimental replicas used in this study comprised two sub-collection ([Figure 1](#)).
173 The first sub-collection includes 10 handaxes knapped by three expert knappers, including Bruce
174 Bradley (n=4), John Lord (n=3), and Dietrich Stout (n=3) ([Stout et al., 2014](#)). These handaxes
175 were made for previous research projects, which similarly aimed to approximate ‘Late Acheulean’
176 handaxes explicitly comparable to the Boxgrove assemblage ([Faisal et al., 2010; Stout et al., 2014;](#)
177 [Stout et al., 2011](#)). The second sub-collection is produced from a 90-hour handaxe knapping skill
178 acquisition experiment ([Bayani et al., 2021; Pargeter et al., 2020; Pargeter et al., 2019](#)), where 30
179 adults with no previous experience in knapping were recruited from Emory University and its
180 surrounding communities and requested to make 132 handaxes in total. Among these 30 adult
181 participants, 17 have gone through multiple one-to-one or group training sessions that amounted
182 to 89 hours in maximum, while the remaining 13 were assigned to the controlled group, where
183 no formal training is given. As part of the preparation efforts, the experimental team spalled
184 the Norfolk flints acquired through [Neolithics.com](#) into flat blanks of similar size and shape for
185 training and assessments. The mechanical properties of these raw materials are comparable to
186 the ones used in Boxgrove in that they are both fine-grained and highly predictable in fracturing
187 process.

188 In the knapping skill acquisition experiment, all research participants participated in the initial
189 assessment (assessment 1 in our data set) before formal training, where they each produced a
190 handaxe after watching three 15-minute videos of Late Acheulean style handaxes demonstrated
191 by expert knappers and examining four Late Acheulean style handaxe replicas from our expert
192 sample. Training was provided by verbal instruction and support from the second author, an
193 experienced knapping instructor ([Khreisheh et al., 2013](#)) with 10 years knapping practice and
194 specific knowledge of Late Acheulean technology including the Boxgrove handaxe assemblage.
195 She was present at all training sessions to provide help and instruction to participants. All train-
196 ing occurred under controlled conditions at the outdoor knapping area of Emory’s Paleolithic
197 Technology Lab, with knapping tools and raw materials provided. All participants were instructed
198 in basic knapping techniques including how to select appropriate percussors, initiate flaking
199 on a nodule, maintain the correct flaking gestures and angles, prepare flake platforms, visualize
200 outcomes, deal with raw material imperfections, and correct mistakes. Handaxe-specific instruc-
201 tion included establishment and maintenance of a bifacial plane, cross-sectional thinning, and

202 overall shaping. The training emphasized both aspects of handaxe making technical skill (the
203 importance of producing thin pieces with centered edges) as well as mental template related
204 markers (symmetrical edges).

205 Subsequently, the 17 participants in the experimental group were assessed after every ten hours
206 of the cumulative learning period, where each of them was requested to produce a handaxe for
207 expert knapper's (N. Khreisheh) review, leading to the compilation of a data set composing 9
208 assessments in total. It should be also noted that 6 out of 17 participants dropped out of the
209 research before the final assessment due to personal reasons. To detect the effect of training
210 on skill level and mental template, we reorganized our assessment classification scheme and
211 combined it into three broader categories, namely pre-training (assessment 1), early training
212 (assessment 2-5), and late training (assessment 6-9), which helps increase the sample size of
213 the measured intervals. A more detailed experimental protocol can be assessed in one of our
214 published papers ([Pargeter et al., 2019](#)).

215 **2.3 Lithic analysis**

216 To better understand the morphological variation of Boxgrove handaxe collection, we adopted a
217 standardized analytical procedure to extract the morphometric information from 752 photos of
218 the studied samples ([Iovita & McPherron, 2011](#)), which include both the front and lateral views
219 of a given specimen. First, we used Adobe Photoshop to conduct a batch transformation of
220 the samples' pixel scale into a real-world measurement scale based on the fixed photographic
221 setting. This is then followed by the batch conversion of color photographs to a black-and-white
222 binary format. Subsequently, we cropped the silhouettes of handaxes one by one using the
223 Quick Selection Tool in Adobe Photoshop. The metric measurements were conducted in ImageJ
224 ([Rueden et al., 2017](#)), where we employed a custom ImageJ script ([Pargeter et al., 2019](#)) to mea-
225 sure the maximum length, width, and thickness of a given silhouette. The width and thickness
226 measurements are taken at 10% increments of length starting at the tip of each handaxe (**Figure**
227 [2](#)), which eventually leads to 19 morphometric variables in total (1 length measurement, 9 width
228 measurements, and 9 thickness measurements). Finally, we calculated the geometric means of all
229 19 linear measurements to create a scale-free data set that preserves the individual morphological
230 variation at the same time ([Lycett et al., 2006](#)). This allometric scaling procedure controls for size
231 variation which may come from initial blanks and/or reduction intensity (shaping/resharpening).

232 Notably, Shipton and Clarkson (2015) previously found that reduction intensity does not have a
233 strong impact on the shape of handaxes. The same procedure was also applied to the morphome-
234 tric analyses of the experimental handaxe collection, which was partially published in Pargeter et
235 al. (2019).

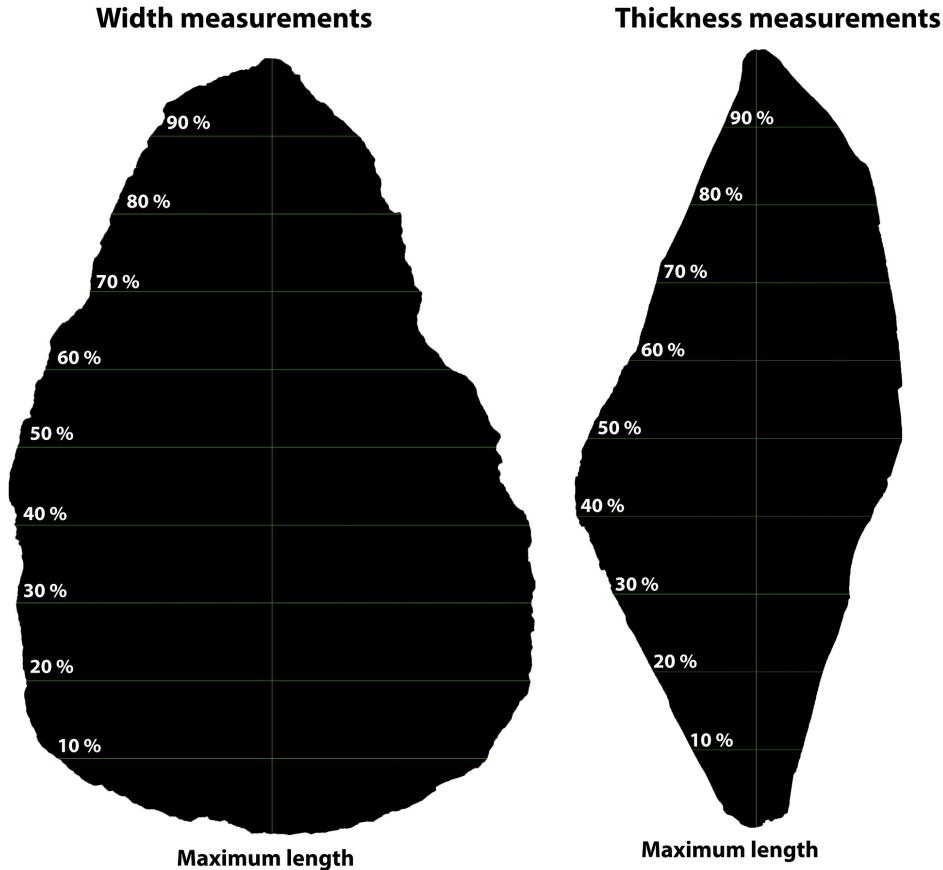

Figure 2: A visual demonstration of the handaxe measurement protocol using Image J (after Pargeter et al. 2019: Figure 5).

236 2.4 Statistical analyses

237 We use the statistical programming language R 4.1.1 (R Core Team, 2021) to conduct statistical
238 analyses and data visualization in this study, particularly the R packages “FactoMineR” (Lê et
239 al., 2008) and “ggstatsplot” (Patil, 2021). As the initial step, simple visualization techniques such
240 scatter plots are frequently used to explore the relationships between variables of interest. Given
241 the number of variables involved in this study, we used principal component analysis (PCA) to
242 reduce the dimension and identify the possible patterns in this morphometric data set, which
243 is one of the most used techniques in similar studies (García-Medrano, Maldonado-Garrido, et
244 al., 2020; García-Medrano, Ashton, et al., 2020; Herzlinger et al., 2017; Iovita & McPherron, 2011;

245 Shipton & Clarkson, 2015; Stout et al., 2014). To detect the effect of training on novices' perfor-
246 mance as compared with archaeological samples and handaxe made by experts, we also compare
247 the corresponding metrics built on PCA across different training periods and across all groups
248 using the Games-Howell nonparametric post-hoc test. Compared with other nonparametric tests
249 frequently used in archaeological research for multiple group comparison such as Tukey's test,
250 Games-Howell test does not rely on the assumptions of sample normality, and equal sample sizes
251 and equal variance are not necessary conditions to perform this test. The sample size of each
252 compared group can be as low as 6 (Games & Howell, 1976; Sauder & DeMars, 2019). Lastly, we
253 compare the delta weight, as defined by the difference between initial nodule weight and end
254 product weight, between these groups to understand the effect of training on reduction intensity.
255 This study adheres to the principles of reproducibility and data transparency of archaeological
256 research by depositing all the codes and data sets involved in an open-access online repository
257 (Marwick, 2017), which are available as supplementary materials and can be accessed through
258 the author's Github (<https://github.com/Raylc/Boxgrove-Exp>).

259 3 Results

260 3.1 Principal component analysis

261 Our analysis suggested that the first two components already explain 77.2% of the variation for the
262 entire morphometric data set composed of 19 variables (Figure 3), which is a rather reasonable
263 variance ratio to avoid overfitting. Variable loadings (Table 1) indicate that the first principal
264 component (PC1) captures relative cross-sectional thickness ("refinement"). It is positively corre-
265 lated with all thickness measurements while negatively correlated with all other measurements.
266 A higher PC1 value thus indicates a handaxe that is thicker relative to width and length, and vice
267 versa. The second principal component (PC2) tracks elongation and pointedness, as indicated
268 by a positive covariance of maximum length and bottom width/thickness. As PC2 increases, a
269 handaxe will be relatively longer and more convergent from the broad base to the tip. Thus, PC1
270 corresponds to cross-sectional thinning and PC2 to a narrowing of the tip relative to length and
271 base dimensions.

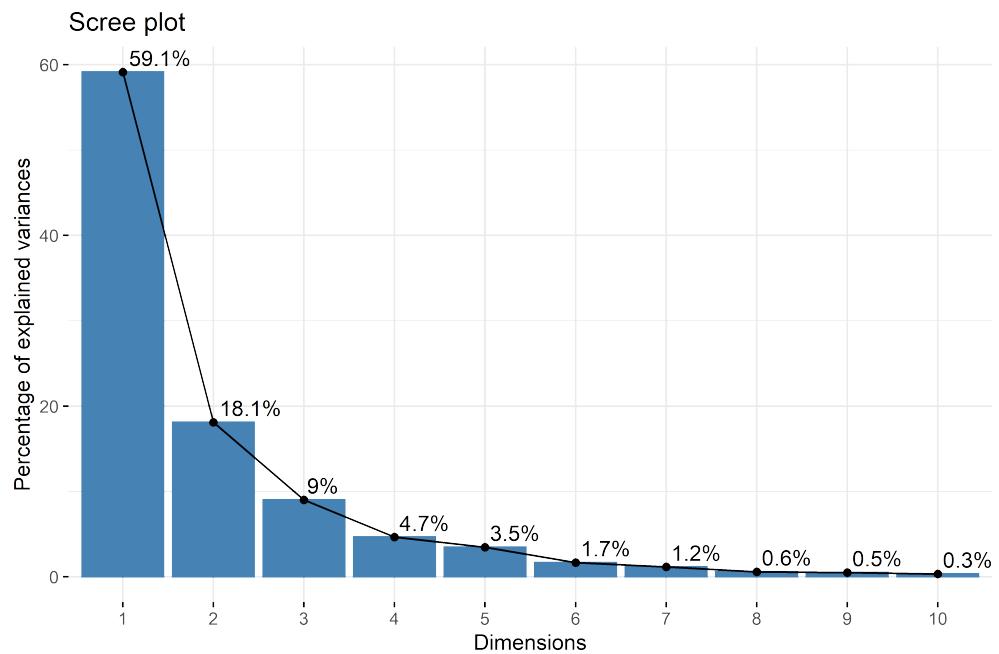

Figure 3: A scree plot showing the percentage of explained variances of the first 10 principal components.

Table 1: Variable loadings for the first two principal components. PC1 (Dim.1) is positively correlated with all thickness-related variables and negatively correlated with all width-related variables and the maximum length. PC2 (Dim.2) is positively with bottom width and thickness variables as well as the maximum length and negatively correlated with width and thickness variables of the tip area.

Variables	Dim.1	Dim.2

max_length	-0.3626	0.2507

272 A closer look at the principal component scatter plot ([Figure 4](#)) yields the clustering of different
 273 groups of handaxes. The majority of Boxgrove handaxes occupy an area featuring negative values
 274 of both PC1 and PC2. The expert group is similar to the Boxgrove group in PC1, while the former
 275 has a relatively higher PC2 value than the latter on average. The group of novice displays the
 276 highest ranges in both PC1 and PC2 values according to the scatter plot, however, it is rather
 277 pronounced that most handaxes made by novices have a positive PC1 value that is different from
 278 both the groups of Boxgrove and experts.

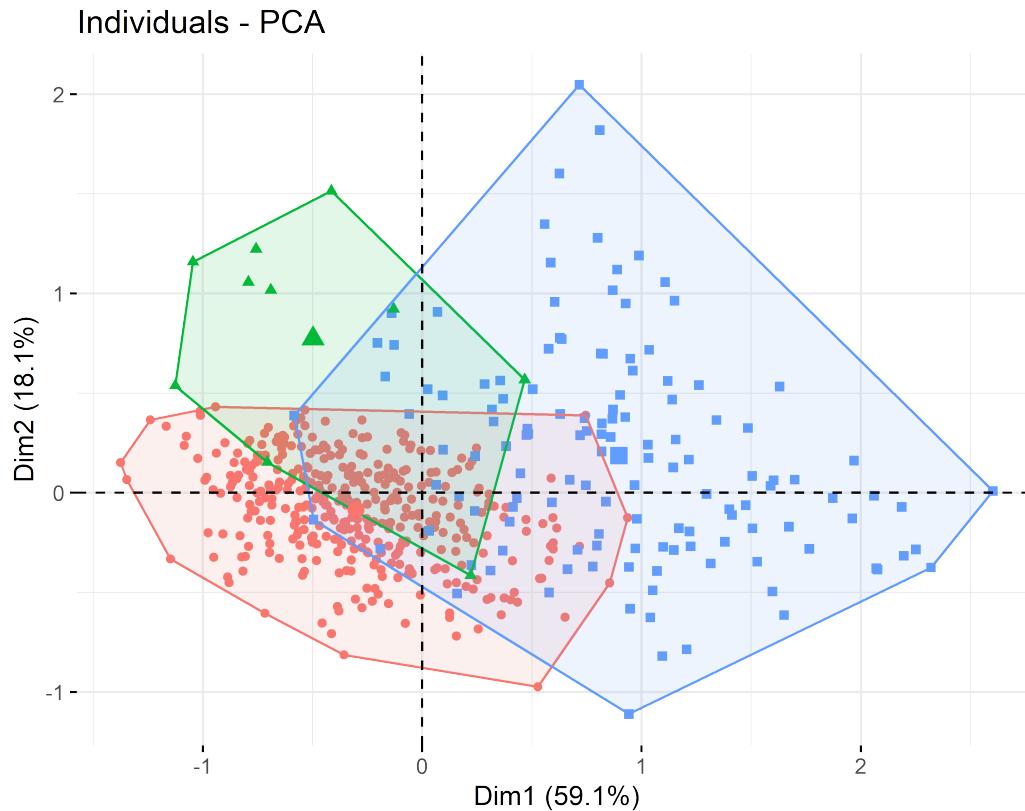

Figure 4: A principal component scatter plot of handaxes from the groups of Boxgrove (red, n=326), expert (green, n=10), and novice (blue, n=132).

279 In addition, visual inspection of the principle component scatter plot (**Figure 4**) suggested that
 280 PC1 and PC2 might be negatively correlated within the Boxgrove and Expert groups. To test this,
 281 we conducted a series of exploratory plotting and statistical analyses of the PC values of three
 282 groups analyzed in our analysis (**Figure 5**). Across all three groups, a negative correlation has
 283 been displayed between the PC1 and PC2 values, although this trend is not statistically significant
 284 ($r=-0.41$, $p= 0.24$) in the expert group, probably because of its small sample size.

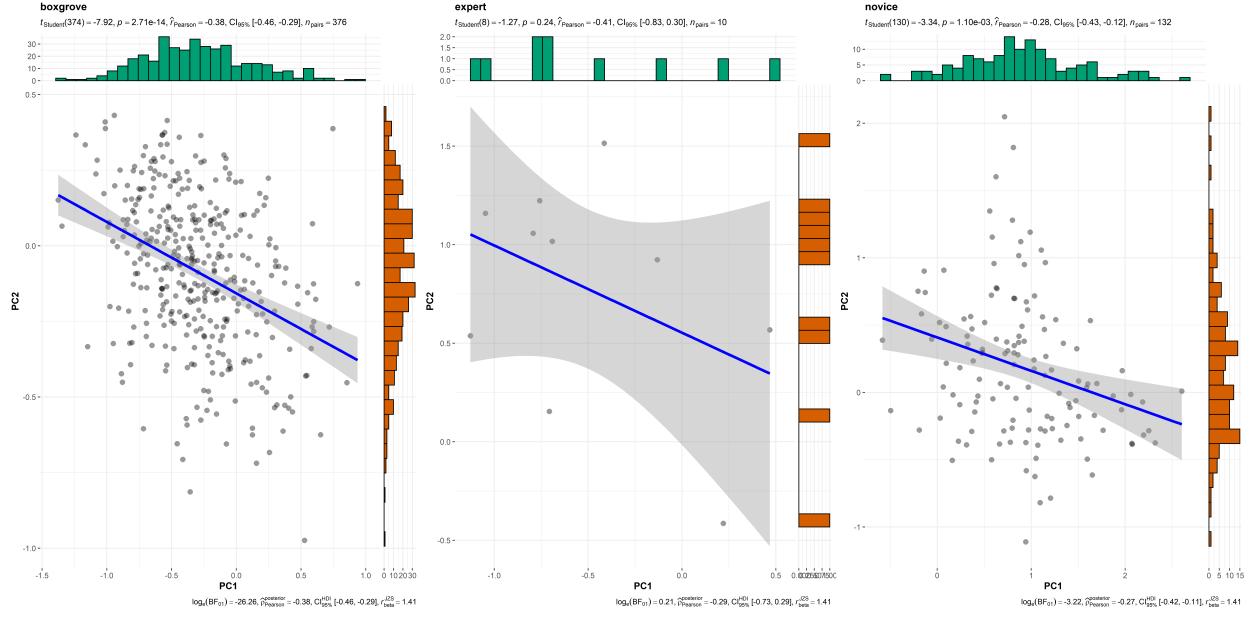

Figure 5: A scatter plot showing the correlation between PC1 and PC2 respectively in the groups of Boxgrove (left, $n=326$), expert (middle, $n=10$), and novice (right, $n=132$). The upper left area in each individual plot displays statistical reporting from a frequentist perspective, including the student-t test statistics, p-value, Pearson correlation coefficient, confidence interval, and sample size. The lower right area in each individual plot displays statistical reporting from a Bayesian perspective, including the natural logarithm of Bayes factor, posterior type and estimate, credible interval, and prior type and value.

285 3.2 Effects of training

286 We extracted the PC1 and PC2 values of individual handaxes and compared them between
 287 different groups, where the novice group was divided into three sub-groups based on their
 288 training stages as specified in the method section. As such, we found that for PC1 values (**Figure**
 289 **6**), the only two group comparisons that are **not** statistically significant are the one between
 290 Boxgrove and Expert ($t = -1.65$, $p > 0.05$) and the one between Early training and Late training
 291 stages ($t = -0.649$, $p > 0.05$), which at least partially confirms our visual observation of the
 292 general PCA scatter plot. Likewise, for PC2 values (**Figure 7**), the group comparison between
 293 the Early training and Late stages again is not statistically significant ($t = 0.333$, $p > 0.05$). An
 294 unexpected result is that the mean PC2 value difference between the Pre-training group and
 295 Boxgrove is also not statistically significant ($t = -0.818$, $p > 0.05$). These results essentially
 296 suggest that there is a significant difference between the pre-training group and post-training
 297 groups in both PC1 (thinning) and PC2 (pointedness). However, the effects of training across
 298 different assessment periods on both dimensions are not significant. Regarding the delta weight
 299 of different groups, our analysis (**Figure 8**) suggests that there is a significant difference between
 300 the pre-training group and Late training group, while all other pairwise group comparison results

301 are insignificant. It can also be inferred that the expert group display a higher variability in terms
 302 of delta weight compared with novices.

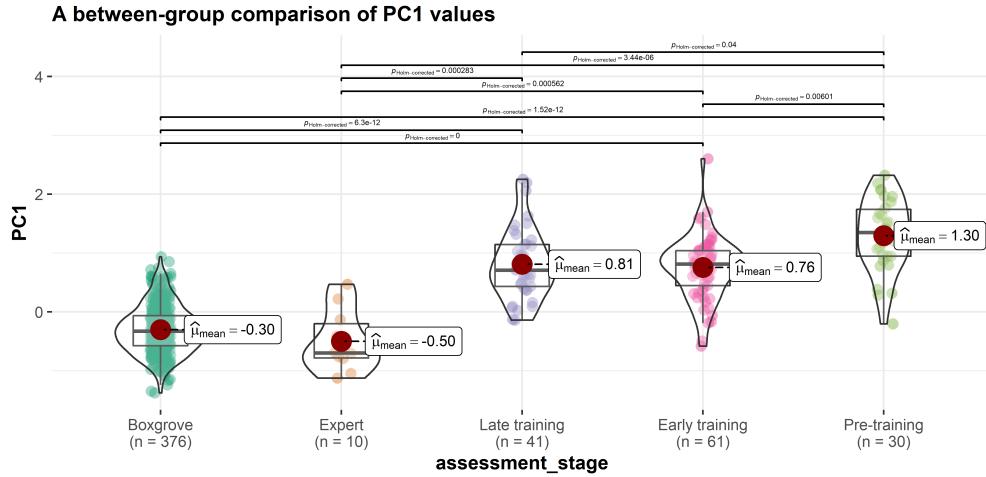

Figure 6: A between-group comparison of PC1 values.

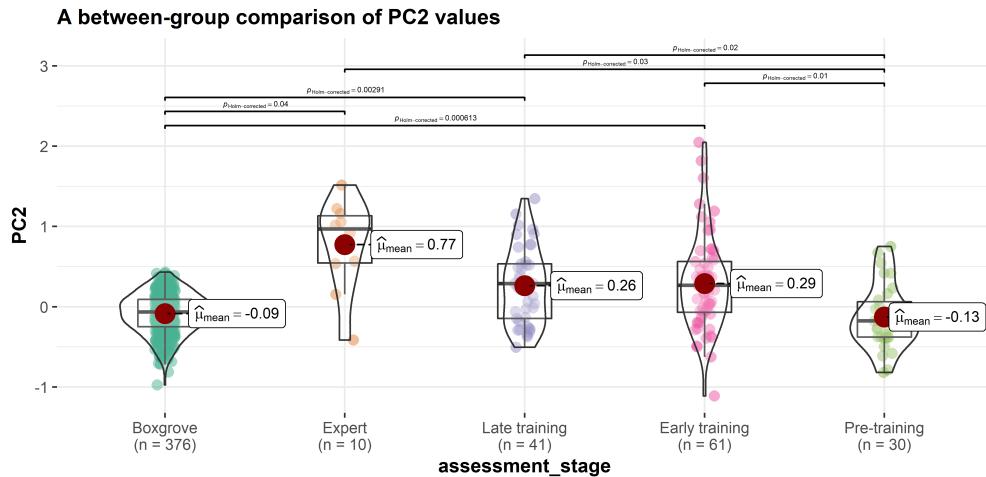

Figure 7: A between-group comparison of PC2 values.

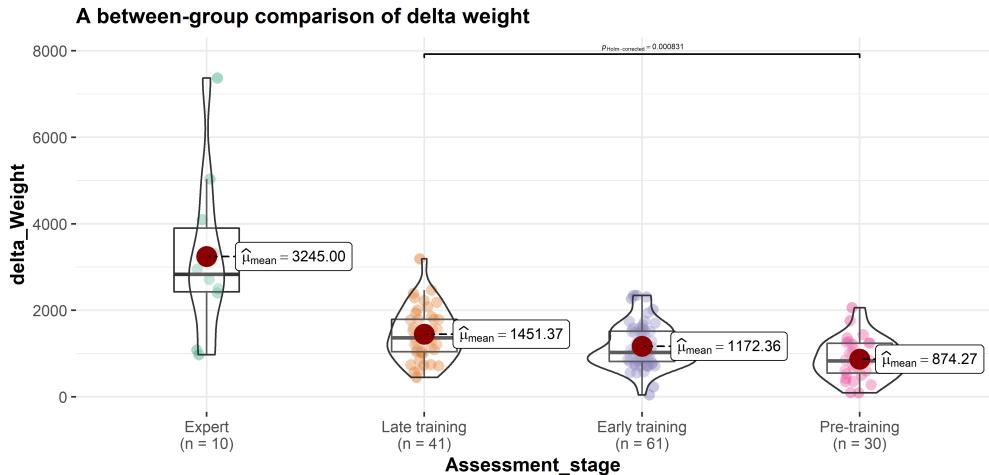

Figure 8: A comparison of the delta weight between the pre-training, early training, late training, and the expert group.

303 4 Discussion

304 Our study suggests that both skill level and mental template have a relatively clear manifestation in
 305 different aspects of handaxe morphology, where the former is related to cross-sectional thinning
 306 (PC1) while the latter relates to handaxe elongation and pointedness (PC2). Moreover, we also
 307 evaluated the effects of training using the data from a 90-hour long knapping skill acquisition
 308 experiment and confirmed the previous finding (2019) that reaching the skill level of modern
 309 experts requires more training time than was permitted in this extensive and long-running
 310 training program. In accordance with the existing literature on handaxe knapping skill (Callahan,
 311 1979; Caruana, 2020; Stout et al., 2014), the results of PCA suggested that PC1 (cross-sectional
 312 thinning) is a robust indicator of skill level as it is a common feature shared by modern expert
 313 knapper and Boxgrove knappers. Thinning is regarded as a technique requiring a high knapping
 314 skill level because it requires one to carefully detach flakes in an invasive manner while not
 315 breaking the handaxe into several pieces, serving the purpose of achieving the desired convexity
 316 and/or volume. This procedure involves precise control of striking forces, strategic choice of
 317 platform external angle, and attentive preparation of bifacial intersection plane, all of which
 318 were part of our experimental training program (Callahan, 1979; Caruana, 2022; Pargeter et
 319 al., 2020; Shipton et al., 2013; Stout et al., 2014). Experimental studies have also shown that
 320 the thinning stage of handaxe produce often involves the use of soft hammers, which is also
 321 supported by indirect archaeological evidence of flake attributes from Boxgrove (Roberts & Parfitt,

322 1998: 384-394; [Roberts & Pope, 2009](#)), although the validity of differentiating purcussor types
323 (hard hammerstone, soft hammerstone, and antler hammer) based on flake attributes has been
324 challenged by other experimental studies([Driscoll & García-Rojas, 2014](#)). It should be noted that
325 both our experts and novices frequently used soft hammers in the production of experimental
326 assemblages. In the skill acquisition experiments, novice knappers were explicitly taught to
327 switch to the soft hammer for thinning purposes, but some of them did not follow the instruction
328 during the assessment. On the other hand, it has also been shown that hard hammers can also
329 be used to achieve similar thinning results ([Bradley & Sampson, 1986](#); [Pelcin, 1997](#)), and the
330 replicas produced by Bruce Bradley in our expert reference collection did not involve the use of
331 soft hammers.

332 Given the dissimilarity of PC2 (elongation and pointedness) values between archaeological and
333 experimental samples and its similarity among modern knappers, we argue that this dimension
334 reflects different mental templates, where the Boxgrove assemblage displays an ovate shape
335 featuring a wider tip while the experimental assemblages are characterized by a more pointed
336 shape with a longer central axis. Our results regarding the ovate plan morphology of the Boxgrove
337 assemblage generally supports what have been reported by Shipton and White ([2020](#)) as well as
338 Garcia-Medrano et al. ([2019](#)). The finding that the expert group has a mental template different
339 from the Boxgrove assemblage is rather surprising since they were requested to mimic Boxgrove
340 handaxes, a potential reason of which could be that these expert didn't have Boxgrove handaxes at
341 hand as model during the manufacture and thus followed their vague memory of a "representative
342 teardrop Late Acheulean handaxe." In general, this pattern may reflect a divergence of group-level
343 aesthetic choices as expected under the theoretical framework of the communities of practice
344 ([Wenger, 1998](#)), which could potentially provide an mechanistic explanation to some macro-
345 level cultural phenomena such as regionalization ([Ashton & Davis, 2021](#); [Davis & Ashton, 2019](#);
346 [García-Medrano et al., 2022](#); [Shipton & White, 2020](#)). The most common form of learning in
347 the experiment occurred in the group condition, where the instructor, as the competent group
348 member, directed the joint enterprise through actively teaching multiple novices at the same time.
349 Meanwhile, novices had the chance to also communicate and learn from their peers, producing a
350 shared repertoire of artifacts and actions. Unfortunately, the handaxe data from the instructor (N.
351 Khreisheh) are unavailable, but it should be noted that the instructor has learned how to knap
352 and how to teach knapping from one of our expert knapper (Bruce Bradley). This cascading effect
353 of social learning might explain why there is a shared mental template between the expert group

354 and the novice group after training.

355 The negative correlation between the PC1 and PC2 values revealed a hidden structural constraint
356 regarding the relationship between cross-sectional thinning and the imposed form. Our results
357 (**Figure 5**) suggested thinner handaxes (low PC1 value) are generally more pointed/less ovate (high
358 PC2 value), which was first reported in Crompton and Gowlett's (1993) pioneering study on the
359 allometry of Kilombe handaxes. In the thinning phase of handaxe making, a knapper must strike
360 flakes that travel more than one half way across the surface while not breaking the handaxe into
361 half (1979: 90). As a corollary, we speculate that it would be easier to perform thinning if the plan
362 shape of a handaxe is narrower and more pointed, echoing the high technological difficulty of
363 making large yet thin bifacial points as perceived by American hobbyist flintknappers (Whittaker,
364 2004: 180-182). It is possible that such constraints help to explain why our novice knappers on
365 average produced more handaxes in similar shapes to those preferred by modern expert knappers,
366 however, this clearly does not explain the design target at Boxgrove. Given the ovate forms of the
367 Boxgrove assemblage, it thus requires a high skill level to overcome this structural constraint to
368 produce thin yet wide handaxes as demonstrated by the Boxgrove knappers. This also provides
369 an alternative explanation to the social transmission of form for the experimental convergence
370 on pointed forms. In this comparative context, it would only be the Boxgrove assemblage that
371 provided evidence of social conformity on a more difficult target shape.

372 In terms of our second research question, this study shows that training does have an immediate
373 intervention effect (pre-training vs. post-training) in both PC1 (skill level) and PC2 (mental tem-
374 plate). Nonetheless, once the training has been initiated, its effects across different assessments
375 on both dimensions are rather non-significant. This finding provides a parallel line of evidence
376 that corroborates what has been suggested in Pargeter et al. (2019) that 90 hours of training for
377 handaxe making is still not enough for novices to reach the skill level as reflected in expert knap-
378 pers, even considering the massive social support involved in the experiment set up including
379 the direct and deliberate pedagogy and the simplified raw material procurement and preparation
380 procedures. Methodologically speaking, this study also demonstrated that the pattern revealed by
381 the multivariate analysis of morphometric data can nicely match with the expert knapper's 5 point
382 grading scale of novices' knapping performances that takes multiple factors into consideration,
383 including outcome, perceptual motor execution, and strategic understanding (See Table 2 of 2019
384 for more details).

385 Moreover, this follow-up project further adds the samples produced by the Late Acheulean
386 toolmaker as a new benchmark to deepen our understanding of this issue. As previously shown
387 in Key's (2019) previous finding regarding Boxgrove, it is noteworthy how constrained the range
388 of Boxgrove assemblage morphological variation is as measured by both PC1 and PC2 even when
389 compared with the modern expert group (Figure 4), especially given the fact that it has the largest
390 sample size among all studied groups. Some potential explanations for this phenomenon include
391 1) the strong idiosyncrasy of individual expert knappers shaped by their own unique learning
392 and practice experience; 2) the present-day skill shortage of our expert knapper as compared
393 with Boxgrove knappers despite their multiple years of knapping practice (Milks, 2019); and/or
394 3) modern knappers' skill level was affected by time constraints when they were requested to
395 produce the reference collections (Lewis et al., 2022; Schillinger et al., 2014b).

396 The pre-training group is unexpectedly similar to the Boxgrove group in PC2 because these
397 novices lack the ability to effectively reduce the nodules, which are typically flat pre-prepared
398 cortical flakes, to the desired form (Figure 9). If the given nodules already possess an oval
399 morphology like those presented in the Boxgrove assemblage, it is likely the form of end products
400 knapped by novices in the pre-training group will remain roughly unchanged (Winton, 2005: 113).
401 This explanation is also supported by the comparison of average delta weight, defined as the
402 difference between the weight of handaxe and the weight of nodule, among four groups, where
403 the pre-training group displays the lowest value (Figure 8). It might be worth noting that the
404 expert group is highly variable probably due to raw material starting size/shape. Achieve handaxe
405 forms while removing as little mass as possible (i.e. making as big a handaxe as possible from
406 the nodule) generally requires a higher skill level due to the reductive or subtractive nature of
407 stone knapping, where correcting an error or any thinning procedure always requires the removal
408 of raw material and thereby reducing the size of a given handaxe (Schillinger et al., 2014a: 130;
409 Deetz, 1967: 48-49). On the other hand, the refitting analyses of the Boxgrove handaxe assemblage
410 have suggested that the nodules exploited by knappers inhabiting this site are somewhat bulky
411 and amorphous (Roberts & Parfitt, 1998: 339, 360). These characteristics have been clearly
412 displayed in a recent attempt of slow-motion refitting of a handaxe specimen from Boxgrove
413 GTP17 (<https://www.youtube.com/watch?v=iS58MUJ1ZEo>). As such, we infer that behind
414 the resemblance of the pre-training group and the Boxgrove assemblage in PC2 are two types of
415 mechanisms that are fundamentally different from each other, where the latter group exhibits
416 a complex suite of cognitive and motor execution processes to transform the shapeless raw

⁴¹⁷ materials to a delicate end product in a given shape.

Figure 9: Core 63 before (left) and after knapping(right), showing the minimal morphological change during the knapping process.

⁴¹⁸ Although we are not the first research team to use secondary archaeological data (e.g., [Key, 2019](#)),
⁴¹⁹ we would still like to highlight here that this research project further exemplifies the potential
⁴²⁰ of reusing old archaeological data in digital format to address novel research questions. In this
⁴²¹ paper, the main source of archaeological data is a collection of photos produced and curated
⁴²² more than 10 years ago, and the morphological variation data of the experimental collection are
⁴²³ also derived from photographs instead of remeasurements of the original artifacts. Given the
⁴²⁴ irreversible nature of archaeological excavations, digitized data, be it text, pictures, or videos,
⁴²⁵ often become the sole evidence that is available for certain research questions. Yet, it has been
⁴²⁶ widely acknowledged that the reuse of archaeological data has not received enough attention
⁴²⁷ among researchers in our discipline ([Faniel et al., 2018](#); [Huggett, 2018](#); [Moody et al., 2021](#)). Among
⁴²⁸ many reasons preventing archaeologists from reusing published and digitized data ([Sobotkova,](#)
⁴²⁹ [2018](#)), the lack of a standardized practice of and motivation for data sharing is a prominent one
⁴³⁰ ([Marwick & Birch, 2018](#)). As stated in the method section, we addressed this issue by sharing the
⁴³¹ raw data and the code for generating the derived data on an open-access repository. Another
⁴³² major and legitimate concern of archaeological data reuse is their quality. In terms of this aspect,
⁴³³ we do acknowledge the limitations of relying on photos when it comes to the more detailed

434 technological analysis of stone artifacts, however, our paper shows that finding the appropriate
435 research questions given the data available is key to revealing new novel insights into the studied
436 topic. Moreover, we believe that this type of research has a strong contemporary relevance due
437 to the continued influence of the COVID-19 on fieldwork-related travel and direct access to
438 archaeological artifacts (Balandier et al., 2022; Ogundiran, 2021).

439 5 Conclusions

440 Regarding the two research questions we proposed in the beginning, our case study suggested that
441 1) we can delineate the effects of skill level and mental template through the multivariate analysis
442 of morphometric data, where the former is associated with cross-sectional thinning while the
443 latter is reflected in elongation and pointedness; 2) On average training has an immediate effect of
444 making novices to better understand the shared design targets, but 90 hours of training is still not
445 enough for novice to reach the level of expertise as reflected in modern experienced knappers, let
446 alone the Boxgrove tool makers. At a larger theoretical level it questions the distinction between
447 social learning of design targets vs. individual learning of the skills needed to achieve them. To
448 illustrate, a thin cross section could be part of a mental template or design target and was explicitly
449 instructed by our expert instructor to novices, but novices cannot fully understand nor achieve
450 this technological goal due to the constraint of skill level, making it a robust indicator of the latter.
451 Traditionally archaeological experiments speaking to the literature of cultural evolution tend to
452 use handaxe as a model artifact and focus on how copying errors emerge during the transmission
453 of a fixed and static target using transmission chain design and alternative raw materials such as
454 foam (Schillinger et al., 2014b, 2017, 2015). This line of inquiry is generally characterized by high
455 internal validity (causal mechanisms) but low external validity (generalizability to archaeological
456 data). In contrast, our study unpacks the differential reproductions of two major sources of
457 variation and reveals how the development of motor skill during learning is constraining the
458 achievement of the socially learnt design target, through an actualistic experimental setting
459 featuring a higher degree of external validity (Liu & Stout, 2022). In the future, more robust
460 experimental studies are needed to deepen our understanding of the relationship between skill
461 acquisition and the morphological variability of handaxes in the proper developmental context
462 (Högberg, 2018) as well as their implications for the biological and cultural evolution of the
463 hominin lineages.

472 The authors declare that they have no known competing financial interests or personal relation-
473 ships that could have appeared to influence the work reported in this paper.

474 8 Acknowledgements

475 We would like to thank Thomas Jennings and three other anonymous reviewers for their insightful
476 feedback on an earlier draft of this manuscript. This work was supported by funding from
477 the National Science Foundation of the USA (grants SMA-1328567 & DRL-1631563), the John
478 Templeton Foundation (grant 47994), and the Emory University Research Council. The handaxe
479 knapping skill acquisition experiment involved in this study was approved by Emory University's
480 Internal Review Board (IRB study no: 00067237). We would also like to thank Radu Iovita for
481 providing us access to the digital photographs of the Boxgrove handaxe assemblage.
